1 Design and Architecture of *Chirp!*

1.1 Domain model

The domain model comprises four concrete classes and one abstract base class derived from the ASP.NET Identity library. On the *Chirp!* platform, users are represented by the **Author** class. **Author** inherits from **IdentityUser**, which is part of the ASP.NET Identity library. Relationships where one **Author** follows another are represented by the **Follow** class. The **Cheep** class represents messages that an **Author** can make, while responses to those messages are modeled by the **Reply** class.

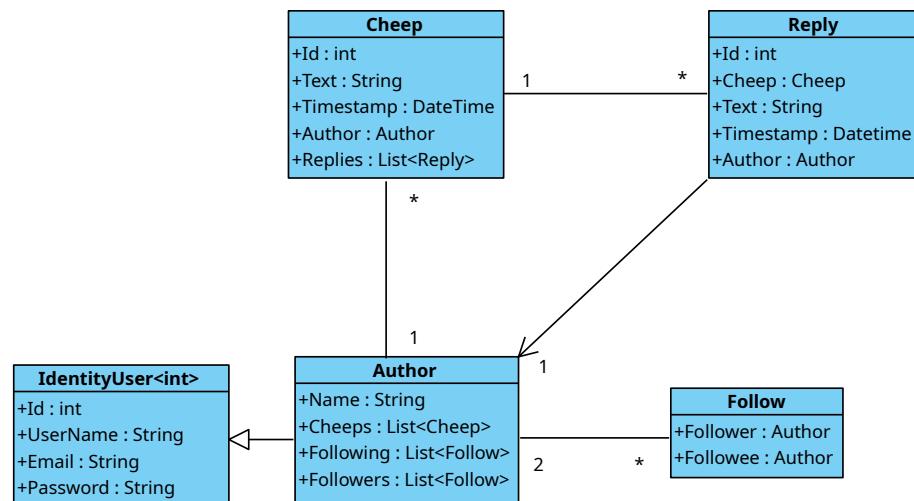

Illustration of the applications domain model

1.2 Architecture - in the small

The project utilizes the onion architecture, and the codebase is organized accordingly. The organization of the code base can be seen in the diagram below:

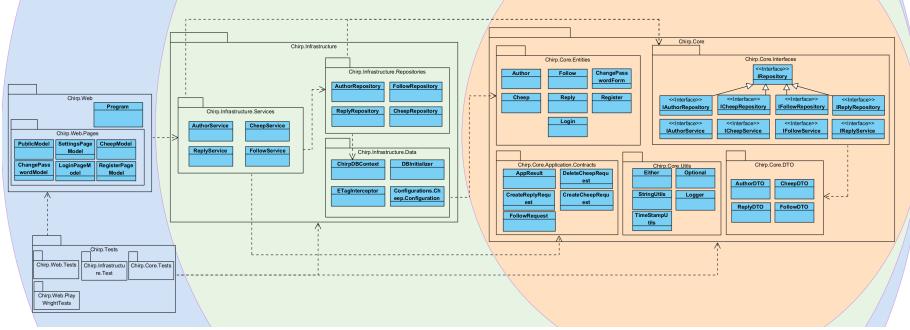

Illustration of architecture and organization of the codebase. The innermost layer is the Domain layer, followed by the Repository layer and Services layer as one combined layer, and finally the UI layer

The distinction between the repository and service layers is not strictly enforced, resulting in some overlap of responsibilities. Since the repository and service layers overlap in responsibilities, they can be considered as a single combined layer, resulting in a three-layered diagram as seen above. Nonetheless, the architecture still adheres to the onion architecture in the sense that all dependencies point inwards.

As shown in the diagram above, **Chirp.Core** comprises the domain model, data transfer objects, domain interfaces, and other domain-specific objects. **Chirp.Infrastructure** contains the implementations of the domain interfaces in the form of loosely coupled services and repositories. It also contains the data model and database context. **Chirp.Web** contains the actual web application (the Razor Page application), which includes the web frontend and UI logic that utilizes the services implemented in **Chirp.Infrastructure**.

1.3 Architecture of deployed application

The diagram below shows the deployment architecture of the application. The application follows a client-server architecture. The server component is a monolith deployed on Microsoft Azure. The server processes incoming requests, interacts with its integrated SQLite database, and sends back responses. The web browser component on the user's device acts as the client and is capable of exchanging requests and responses with the server over HTTPS, and rendering the received data to the user.

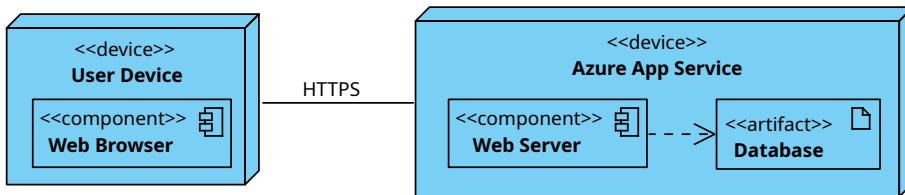

Illustration of the architecture of the deployed application

1.4 User activities

For any Chirp! user, the entry point to the application is the root page, which displays the public timeline. This timeline shows all posted Cheeps sorted in order of the most recent cheeps first. Unauthorized users can browse the public timeline and view individual authors' timelines, but they are not able to interact with cheeps or authors in any way. To gain access to the rest of the features, users must authenticate by registering and/or logging in, as illustrated in the diagram below:

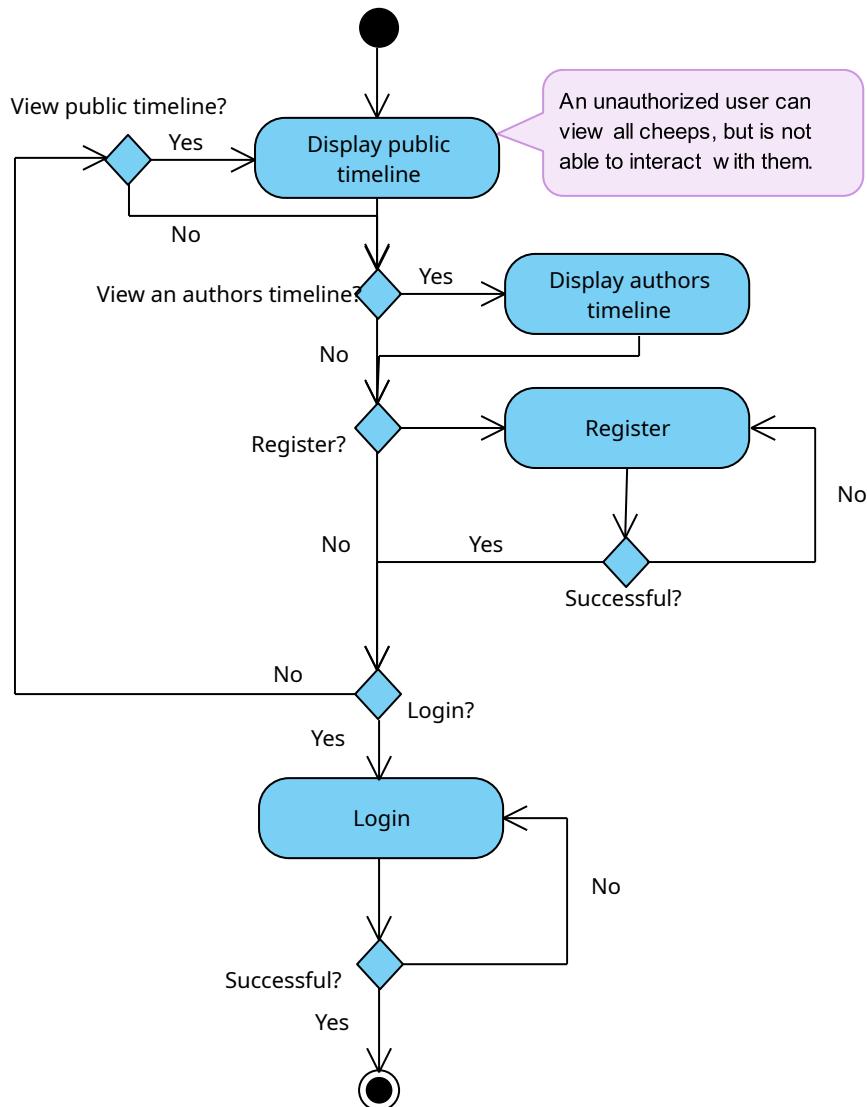

Illustration of a typical unauthorized user's journey through the application before and during authentication

An authorized user is able to post cheeps, reply to cheeps and follow other authors. They are also able to view their own private timeline. The private timeline contains the users own cheeps, and cheeps from authors they have

followed. Authorized users are also able to access their account settings, which allows them to change their password (if they are not signed up with OAuth) and deleting their account.

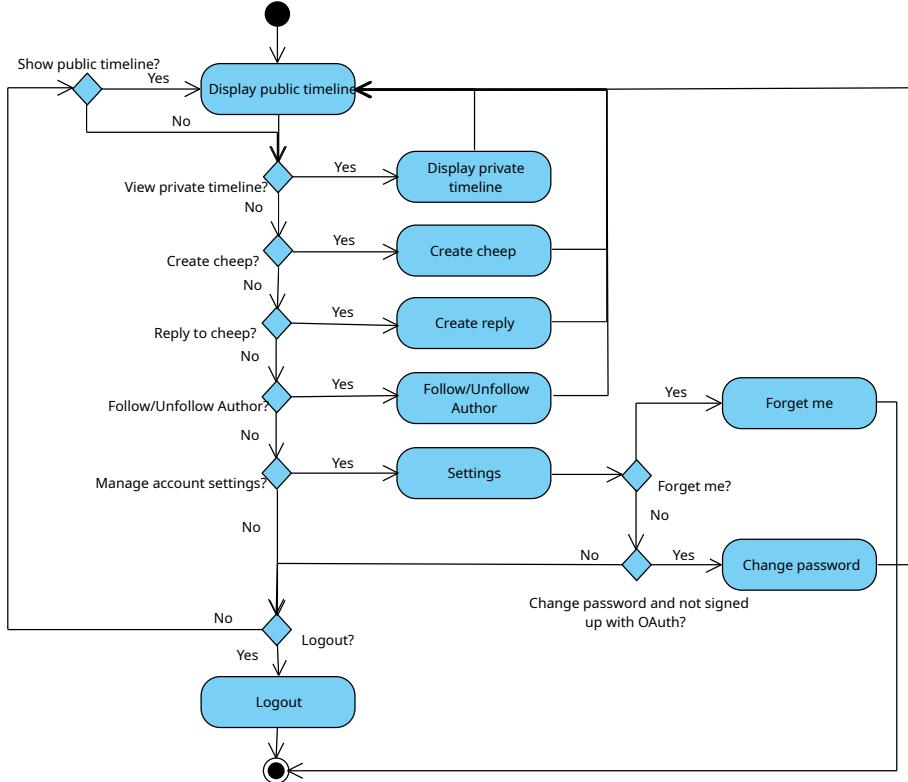

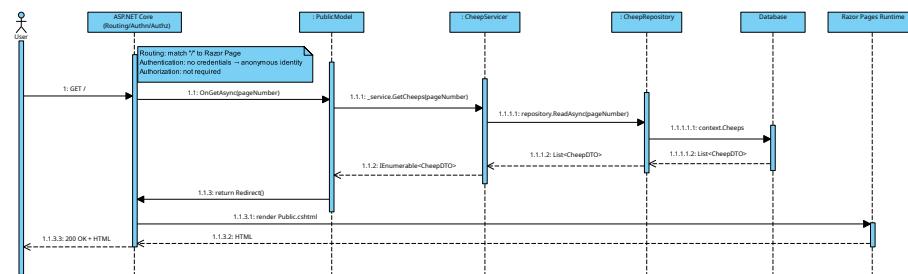

Illustration of a typical authorized user's journey through the Chirp! application

1.5 Sequence of functionality/calls trough *Chirp!*

The diagram shows the request flow for the public Razor Page in ASP.NET Core. A user initiates a GET / request, which is routed through the ASP.NET Core middleware pipeline and dispatched to `PublicModel.OnGetAsync()`. The page model retrieves data by calling the application service, which in turn queries the repository backed by the database. The resulting data is returned to the page model, the Razor view `Public.cshtml` is rendered, and the generated HTML is sent back to the user as a 200 OK response.

Sequence diagram of the flow of messages and data through the Chirp! application

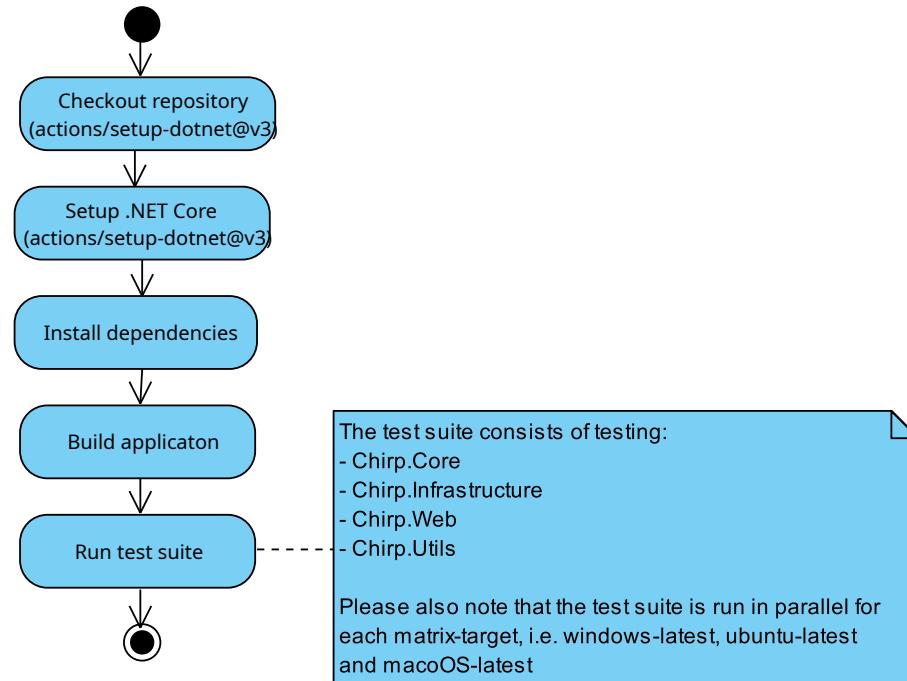

from an unauthorized user's perspective

2 Process

2.1 Build, test, release, and deployment

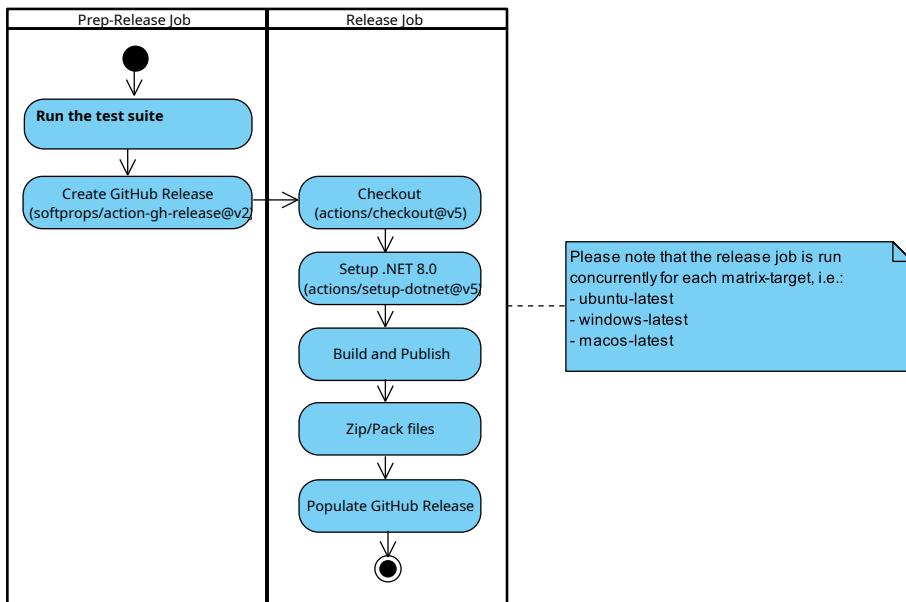

The application is built, tested, released, and deployed automatically using GitHub Actions workflows. These workflows are illustrated below in the UML activity diagrams. Please also note that if any step of a workflow fails during execution, the entire workflow is aborted. This is not illustrated in the diagrams, as it creates too much clutter.

The application is continuously built and tested whenever commits are pushed to branches or when pull requests attempt to merge into the main branch. This ensures that changes are constantly validated and bugs are caught early in the development process:

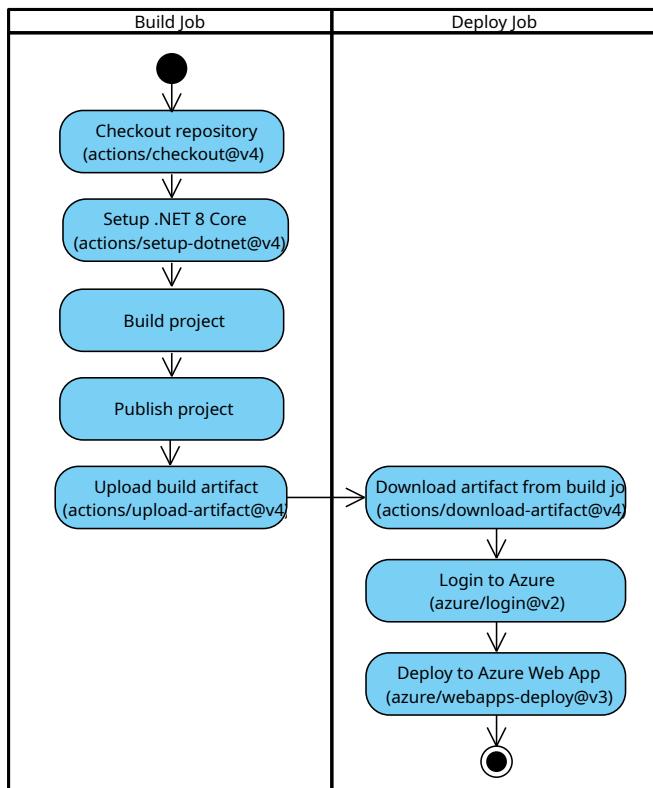

Activity diagram over the build and testing workflow

Commits tagged using the `x.y.z` format, trigger the release workflow. This workflow automatically tests the application on each major platform using the previous workflow. If all the tests succeed, releases are created for Windows, Linux, and MacOS:

Activity diagram over the release workflow

The application is deployed to an Azure App Service when commits are pushed to the main branch:

Activity diagram over the deployment of the application to Microsoft Azure

2.2 Team work

2.2.1 Project board

The image below shows the GitHub project board used to make the status of development visible and transparent during this project:

.TODO

- Chirp #84 Liking other users post

IN PROGRESS

- Chirp #82 Feature - Rechirps

DONE

- Chirp #52 1.c) Constrain Length of Cheeps(to 160 chars)
- Chirp #103 Wrong error message when email is invalid
- Chirp #55 Fix azure deployment
- Chirp #56 1.a) ASP.NET Core Identity - Auth
- Chirp #39 1.c) Add initial testing
- Chirp #13 Refactor the database implementation so it uses a serializable internal datastructure

Screenshot of the GitHub project board

As shown on the project board, most of the issues have been completed. The remaining issues concern the implementation of additional custom features that were identified as nice-to-haves during development but were not implemented.

2.2.2 Development process

Our group follows a simple and structured development workflow from issue creation to feature integration. When a new issue (something that needs to be worked on) is identified, it is documented as an issue on GitHub in the format of a user story. The issue includes a clear task description, suitable acceptance criteria, and relevant labels. The issue is then assigned to one or more group members. The assigned developers then implement the required functionality and test it to verify that it meets the acceptance criteria. Once the work is completed, a pull request is opened against the main branch. Before the pull request is merged, it is automatically reviewed by CodeFactor and at least one team member. If the reviewer(s) approve the changes, the pull request is merged into the main branch. If any issues are identified during code review, the developers revise their implementation and repeat the testing and review process until it is approved. The flow can be seen in the activity diagram below:

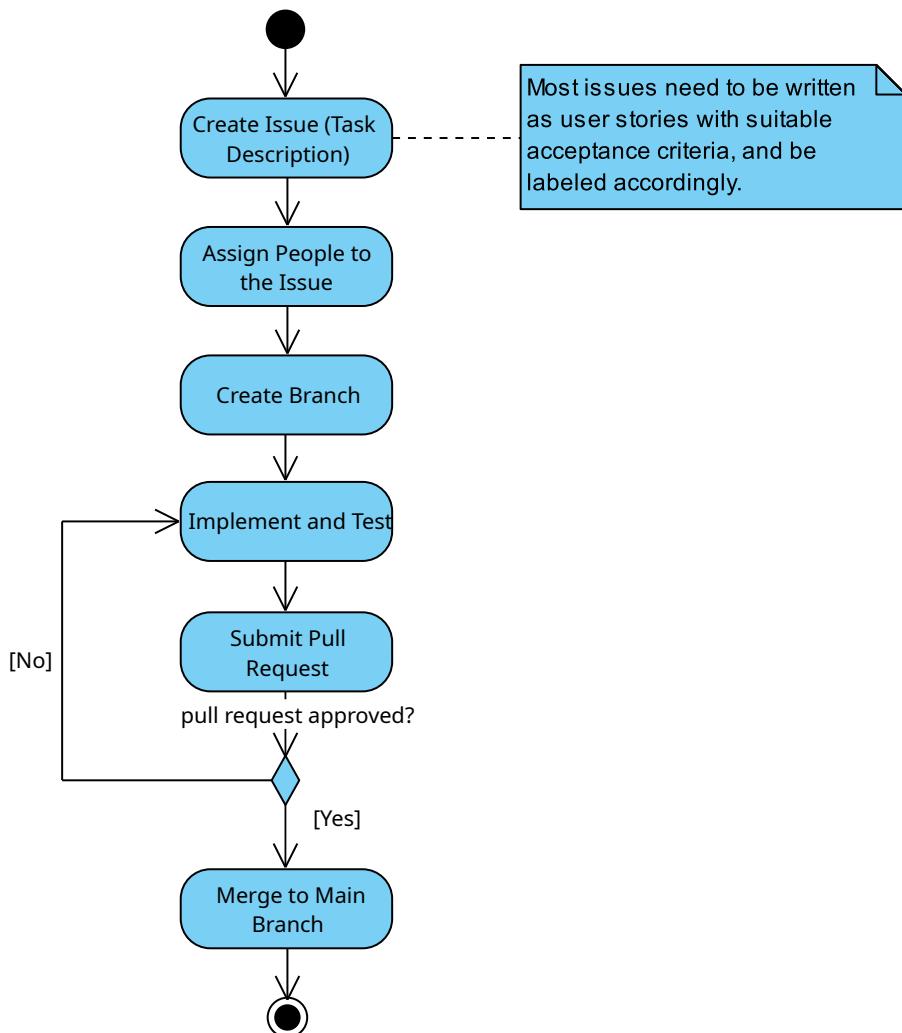

Illustration of the flow of activities that happen from the creation of an issue (task description) until a feature is finally merged into the main branch

2.3 How to make *Chirp!* work locally

2.3.1 Prerequisites

The *Chirp!* application has the following dependencies that must be installed for the application to run:

- `dotnet-runtime-8.0`
- `dotnet-sdk-8.0`
- `aspnet-runtime-8.0`

2.3.2 Cloning the Repository

To run the application locally, first clone the repository. One way to do this is by cloning it via HTTPS from the terminal:

```
git clone https://github.com/ITU-BDSA2025-GROUP4/Chirp.git
```

2.3.3 Running the Application

The application can now be compiled and run using the following command from the repository root:

```
dotnet run --project src/Chirp.Web
```

The application will start listening on a local URL printed in the terminal. By default this is `localhost:5273`.

2.3.4 GitHub OAuth

By default GitHub OAuth will **not** work locally because it requires secrets to be configured. To configure the secrets, one would navigate into the `Chirp.Web` directory, and execute the following commands:

```
dotnet user-secrets init  
dotnet user-secrets set "AUTHGITHUBCLIENTID" "client-id"  
dotnet user-secrets set "AUTHGITHUBCLIENTSECRET" "client-secret"
```

These secrets can naturally not be shared without exposing them to the entirety of GitHub, so to test out the functionality please visit the deployed web app on <https://bdsagroup4chirprazor.azurewebsites.net/>.

2.4 How to run test suite locally

2.4.1 Prerequisites

Some parts of the test suite rely on Playwright. Please ensure that Playwright is installed before running the tests.

2.4.2 Running the tests

Assuming you have local copy of the application repository, the simplest way to run the test suite is to run the helper script from the repository root:

```
./scripts/run_all_tests.sh
```

Note that the app should not be running when invoking this script. Otherwise the end-to-end unit test will fail to start.

You can also run tests individually by navigating to the relevant subdirectory within the test directory and running the .NET test command:

```
dotnet test
```

2.4.3 Description of the test suite

The test suite consists of unit tests and integration tests, which are found within `test/Chirp.Core.Tests` and `test/Chirp.Infrastructure.Tests`. These tests ensure the correctness of core application logic and its interaction with infrastructure components. Additionally, the test suite contains end-to-end tests and UI tests, which are located in `test/Chirp.Web.Tests` and

`test/Chirp.Web.PlayWrightTests`. These tests verify that the application functions correctly from a user's perspective.

3 Ethics

3.1 License

The project is licensed under the MIT license.

3.2 LLMs, ChatGPT, CoPilot, and others

During the development of this project, several LLMs were used, namely **ChatGPT**, **GitHub Copilot** and **Google Gemini**. The models were used to support the development of the project, but not as substitutes for our own problem-solving, i.e., they were primarily used for suggesting implementations, clarifying syntax and language-specific features, and proposing alternative approaches to problems. GitHub Copilot was additionally used during code reviews as an automated tool that provided suggestions and caught bugs. When LLM-generated code was used, the involved LLMs were typically credited as co-authors in a relevant commit.

Overall, the responses from the LLMs were *moderately* helpful. While they rarely produced fully functional code that could be integrated into the project without modification, they were very effective at pointing development in the right direction and offering different perspectives on problems. In this capacity, the LLMs thus functioned as an on demand TA. This helped speed up the project's development, as having a sparring partner who continuously provided feedback helped with solving problems more efficiently.
